Supporting Information

ABSTRACT: Aqueous, two-phase systems (ATPSs) may form upon mixing two solutions of independently water-soluble compounds. Many separation, purification, and extraction processes rely on ATPSs. Predicting the miscibility of solutions can accelerate and reduce the cost of the discovery of new ATPSs for these applications. Whereas previous machine learning approaches to ATPS prediction used physicochemical properties of each solute as a descriptor, in this work, we show how to impute missing miscibility outcomes directly from an incomplete collection of pairwise miscibility experiments. We use graph-regularized logistic matrix factorization (GR-LMF) to learn a latent vector of each solution from (i) the observed entries in the pairwise miscibility matrix and (ii) a graph where each node is a solution and edges are relationships indicating the general category of the solute (i.e., polymer, surfactant, salt, protein). For an experimental data set of the pairwise miscibility of 68 solutions from Peacock et al. [*ACS Appl. Mater. Interfaces* 2021, 13, 11449–11460], we find that GR-LMF more accurately predicts missing (im)miscibility outcomes of pairs of solutions than ordinary logistic matrix factorization and random forest classifiers that use physicochemical features of the solutes. GR-LMF obviates the need for features of the solutions and solutions to impute missing miscibility outcomes, but it cannot predict the miscibility of a new solution without some observations of its miscibility with other solutions in the training data set.

INTRODUCTION

Aqueous, Two-Phase Systems (ATPS). Aqueous, two-phase systems (ATPS)^{1–3}—also known as aqueous biphasic systems (ABS)—may form upon mixing the solutions of two independently water-soluble compounds (e.g., polymers, surfactants, or salts), resulting in a phase separation owing to incompatibility of the compounds.⁴ (Figure S1 shows an example ATPS⁵ for readers who are unfamiliar with this phenomenon.) Beijerinck observed the first ATPS, an incompatible mixture of aqueous starch and gelatin solutions, in 1896.⁶ Today, ATPSs are widely used for separation, purification, and extraction of biomolecules⁷ for biotechnology applications,⁸ metals,^{9,10} and environmental contaminants.¹¹ In general, ATPSs can be used as a green alternative to organic-aqueous solvent extraction.¹²

Although ATPS-based separations are sufficiently simple to perform in an undergraduate teaching laboratory,¹³ predicting whether two solutions will form an ATPS is challenging. The fundamental thermodynamics of ATPS are reasonably described by Flory–Huggins theory.^{4,14,15} However, accurately obtaining/predicting the solute–solute and solute–solvent

interaction parameters is challenging for both experiment and atomistic simulation.^{16,17} Direct molecular dynamics simulations of liquid mixtures to predict ATPS formation are computationally expensive, predicated on an accurate force field, and require an order parameter to detect the separation.¹⁸ Alternatively, machine learning can be used to predict miscibility from the experimental data. One approach is to machine-learn the Flory–Huggins parameters,¹⁹ but this assumes that Flory–Huggins theory captures all of the relevant thermodynamics for miscibility. Instead, one could predict miscibility directly, i.e., whether two solutions give rise to an ATPS. Peacock et al. recently published a data set of ATPS outcomes for 2278 pairwise mixtures of 68 water-soluble compounds,²⁰ using a microscopy-based high-throughput

assay.²¹ They used this data to train a random forest to predict the (im)miscibility of pairs of solutions from physicochemical features of the solutes, drawn from PubChem.²² The random forest achieved an ~74% accuracy. (Some closely related but distinct problems in machine learning for aqueous phase thermodynamics include predicting the partition coefficient of biomolecules in the two different phases of an ATPS^{23–25} and predicting the phase behavior of one surfactant in water as a function of temperature and surfactant concentration.²⁶)

Matrix Factorization. The pairwise structure of ATPSs suggests the possibility of imputing missing or unobserved mixture miscibilities using matrix factorization. A classic example of matrix factorization for data imputation is in recommending movies to users based on a limited set of movie ratings by users.^{27,28} The collection of ratings is organized into a matrix, whose rows and columns pertain to the users and movies, respectively. This matrix is sparsely populated, and the missing entries are the ratings we wish to predict for making movie recommendations. By assuming that the movies and users can be represented by low-dimensional latent vectors that can be learned from the observed ratings, one can factorize the ratings matrix. Conceptually, the underlying latent vectors representing the movies could include dimensions indicating seriousness vs escapist, historical vs futuristic, romantic vs unromantic, etc., and the latent vectors of the users represent their affinities toward those types of movies.^{27,28} To learn the low-rank latent representation of the movies and users, MF needs a few example ratings; this requirement for a *new* movie or user is known as the “cold-start problem”.²⁷

Matrix factorization approaches have been applied to a variety of *chemical systems*, e.g., to predict gas adsorption in nanoporous materials,^{29,30} diffusion coefficients³¹ and activity coefficients^{32–35} of binary liquids, Henry’s law coefficients,³⁶ the synthesis of metal oxides^{37,38} and halide perovskites,³⁹ gas permeabilities in polymers,⁴⁰ and antiviral activities of molecules.⁴¹ In these examples, the rows and columns represent different entities (e.g., gases and sorbents, elements, and reaction conditions) like the movie setting.

Our Contribution. In this paper, we demonstrate matrix factorization for ATPS predictions: imputing unobserved outcomes in a solution miscibility matrix via logistic matrix factorization (LMF).^{27,42,43} An $n \times n$ *incomplete miscibility matrix* organizes pairwise miscibility outcomes of n distinct aqueous solutions; row i and column i pertain to solution i (at some concentration), and entry (i, j) contains the miscibility of solution i and j (0, forms ATPS; 1, miscible; missing, not observed). In contrast to the movie rating matrix, the (square) miscibility matrix is symmetric; its rows and columns pertain to the same entities (solutions). The objective is to leverage the observed values in the miscibility matrix to predict the unobserved (missing) ones. Rather than engineering a set of features of each solution (e.g., physicochemical features of its solute molecule) and then training a machine learning model to use those features to predict the miscibility of the two solutions, LMF instead *learns* a low-dimensional latent vector representation of each solution from the observed miscibility outcomes during the process of training. Then, LMF uses the learned latent representations of the solutions to make predictions (miscible or immiscible (ATPS)) for the unobserved entries. The underlying assumption is that the compound miscibility matrix exhibits a low-rank structure,⁴⁴ owing to underlying chemical/thermodynamic principles

governing miscibility of the solutions and chemical similarities (e.g., functional groups in common) between the compounds.

For the miscibility matrix, the rows and columns both pertain to solutions, but the different types of solutes involved (polymer, proteins, surfactants, and salts) might admit a chemically meaningful grouping. This suggests a modification to LMF to exploit this type of limited information about the categories of solutes by using *graph-regularized* matrix factorization (GR-LMF)⁴⁵—also known as “manifold-regularized”^{46,47} or “neighborhood-regularized”⁴⁸ MF. In this graph, the nodes represent solutes and edges joining pairs of nodes represent pairwise relationships (e.g., “both of these solutes are polymers”). The basic idea behind the graph regularization is to incorporate prior knowledge into LMF learning—that similar categories of solutes tend to exhibit similar miscibility behavior—by promoting vector representations of solutions of similar solutes to be near each other in the latent space. (GR-MF has been applied to single-cell RNA-seq clustering⁴⁹ and predicting drug–drug, drug–target, and metabolite–disease interactions^{48,50–53} and side effects of drugs.⁵⁴) Starting from only (1) incomplete experimental observations of (im)-miscibility of pairs of 68 solutions of distinct compounds from Peacock et al.²⁰ and (2) the rough grouping of the compounds into the categories of polymer, protein, surfactant, or salt, we show that GR-LMF learns latent representations of the solutions that give ATPS predictions on missing entries outperforming (i) ordinary LMF and (ii) a standard supervised machine learning approach using random forest classifiers taking as input physicochemical features of the compounds in the solutions. Like all MF methods, GR-LMF requires a few initial miscibility observations of a new solution to learn an appropriate representation before a prediction can be made.

■ THEORY: GRAPH-REGULARIZED MATRIX FACTORIZATION FOR IMPUTING SOLUTION MISCIBILITY

The general problem and our computational strategy are illustrated in Figure 1.

Problem Setup: Imputing Missing Entries in a Solution Miscibility Matrix. We are interested in the pairwise miscibility of a set of n aqueous solutions at some constant temperature. Each solution consists of a distinct (water-soluble) compound dissolved in water at some compound-specific concentration. (This simplification precludes our model from needing to capture the concentration dependence of the miscibility.) Each compound belongs to a category (e.g., polymer, salt, etc.) defined based on chemical intuition.

The Miscibility Matrix. Let $m_{ij} \in \{0, 1\}$ (0, immiscible and ATPS-forming; 1, miscible) be the miscibility of solution i and j . The $n \times n$ *miscibility matrix* M contains all of the solution miscibilities. Entry (i, j) of M is m_{ij} . Row/column i pertains to the solution of compound i . The matrix M is symmetric because $m_{ij} = m_{ji}$.

The Data. Suppose we have conducted experiments where we have mixed a set of unique unordered pairs of solutions $\Omega_{\text{obs}} \subset \{\{i, j\} : i, j \in \{1, \dots, n\} \wedge i \neq j\} =: \Omega_{\text{all}}$ and observed their miscibilities $\{m_{ij} : \{i, j\} \in \Omega_{\text{obs}}\}$. Importantly, many of the pairwise solution miscibilities have not been observed; i.e., the miscibility matrix M is *incomplete*; the entries $\Omega_{\text{all}} \setminus \Omega_{\text{obs}}$ are missing. Let $\theta := 1 - |\Omega_{\text{obs}}|/|\Omega_{\text{all}}|$ be the fraction of entries that are missing. Further, suppose the solute of each solution belongs to a known category (e.g., polymer, salt, etc.). We

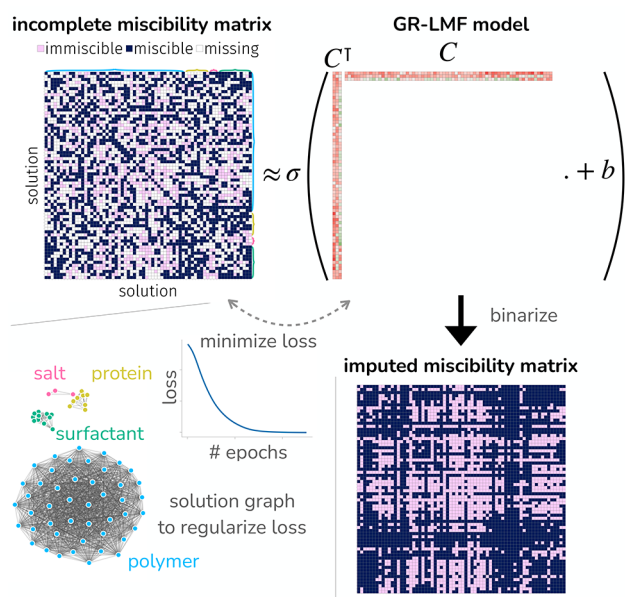

Figure 1. Illustration of our approach. (upper left) Pairwise miscibility observations are organized as a miscibility matrix, M , where the rows and the columns indicate solutions and the entries correspond to miscible, immiscible, or missing observations. (upper right) The GR-LMF method obtains a logistic-transformed low-rank factorization of M , by minimizing a loss function (which includes both the reconstruction loss of the training data and regularization loss from category-based solute similarities; lower left). (lower right) The resulting approximation matrix can be binarized by some threshold to make imputations about unobserved mixing experiments.

represent this information as a simple graph $G = (\mathcal{V}, \mathcal{E})$. The nodes $\mathcal{V} = \{v_1, \dots, v_n\}$ in the graph represent the solutions. The presence of an edge $\{v_i, v_j\} \in \mathcal{E}$ joining nodes v_i and v_j indicates that the solutes of these two solutions belong to the same category; the absence of an edge indicates the two solutes do not belong to the same category. In other words, the edges in solution graph G express the relationships among the solutions in terms of their types of solutes.

Objective. Our objective is to impute the missing entries of the miscibility matrix M , i.e., to predict the values of the unobserved solution miscibilities $\{m_{ij} : \{i, j\} \in \Omega_{\text{all}} \setminus \Omega_{\text{obs}}\}$. To do so, we take a data-driven approach and leverage (i) the observed solution miscibilities $\{m_{ij} : \{i, j\} \in \Omega_{\text{obs}}\}$ and (ii) the graph G indicating the categories to which the compounds belong. Specifically, we will seek a logistic-transformed low-rank factorization of the miscibility matrix M regularized by solution graph G that specifies relationships between its rows/columns.

The Solution Miscibility Model. We propose a probabilistic model for the miscibility of any pair of solutions. The model assumes that each solution i may be represented as a low-dimensional latent vector $c_i \in \mathbb{R}^k$. Conceptually, vector c_i encodes the chemical features of solute i relevant to its compatibility with the other compounds, and it contains information about the concentration of the compound in the specific solution under consideration. (In principle, solutions of the same compound with different concentrations would occupy different rows and columns of M and correspond to different c_i vectors, although one would expect them to point in the same direction. In the Peacock et al. data set, each

compound is present only at a single concentration, so in the present analysis there is a bijection between solution vectors and compounds.)

Given the latent solution vectors $\{c_1, \dots, c_n\}$ and a bias $b \in \mathbb{R}$, our model for the probability that solution i and solution j are miscible is a conditional probability:

$$\pi(M_{ij} = 1 \mid c_1, \dots, c_n, b) = \sigma(c_i \cdot c_j + b) \quad (1)$$

The monotonic sigmoid function $\sigma(x) = (1 + e^{-x})^{-1}$ squashes its input x to its range $(0, 1)$ for interpretation as a probability.

The model in eq 1 admits a geometric interpretation. Note, $c_i \cdot c_j = \|c_i\| \|c_j\| \cos \theta_{ij}$, where θ_{ij} is the angle between solution vectors c_i and c_j in the latent space. Consequently, pairs of solutions whose vectors c_i and c_j point in roughly the same (opposite) direction tend to be miscible (immiscible); i.e., the location of the solution vectors $\{c_i\}_{i=1}^n$ in latent space relative to each other dictates our predictions about their pairwise miscibilities. Changing the magnitude, but not the direction, of a vector c_i increases the model's confidence that the (im)miscibility of solution i with the other solutions j differs from the average outcome, as this does not change the sign of $c_i \cdot c_j$ but increases the magnitude of it; a very large magnitude c_i pushes the output of $\sigma(x)$ to be closer to zero or one. A positive (negative) bias b shifts the predictions toward miscible (immiscible); $\sigma(b)$ roughly corresponds to the fraction of pairs of solutions in the training set that are miscible.

The Matrix Perspective. The model in eq 1 approximates the miscibility matrix as

$$M \approx \sigma \left(\begin{bmatrix} - & c_1^T & - \\ \vdots & \vdots & \vdots \\ - & c_n^T & - \end{bmatrix} \begin{bmatrix} | & & | \\ c_1 & \cdots & c_n \\ | & & | \end{bmatrix} + \begin{bmatrix} b & \cdots & b \\ \vdots & \ddots & \vdots \\ b & \cdots & b \end{bmatrix} \right) \quad (2)$$

where $\sigma(x)$ denotes element-wise operation of the sigmoid function. That is, we approximate the miscibility matrix as a sigmoid-transformed low-rank (rank $\leq k$) matrix factorized as $C^T C$, where the $k \times n$ matrix C contains the latent solution vector i in its column i , plus a constant bias matrix $[b]$. Thus, our miscibility model falls in the “matrix factorization”/“low-rank matrix model” category of machine learning algorithms,^{27,42} more specifically, *logistic matrix factorization*.⁴³

Training vs Imputation Stages. In the *training* stage, we learn the latent vectors of the solutions $\{c_i\}_{i=1}^n$ and the bias b from the *observed* miscibilities $\{m_{ij} : \{i, j\} \in \Omega_{\text{obs}}\}$ and the solution graph G . The dimension k of the latent solution vector space is a hyperparameter specified before training.

In the *imputation* stage, we use the learned $\{c_i\}_{i=1}^n$ and b and the model in eq 1 to predict the *unobserved* solution miscibilities $\{m_{ij} : \{i, j\} \in \Omega_{\text{all}} \setminus \Omega_{\text{obs}}\}$. We employ a threshold t (a hyperparameter) for the classification rule; i.e., the model prediction for the miscibility of compound solutions i and j is

$$\hat{m}_{ij} := \mathcal{I}(\sigma(c_i \cdot c_j + b) > t) \quad (3)$$

with $\mathcal{I} : \mathbb{R} \rightarrow \{0, 1\}$ being the indicator function.

Training. To train the model in eq 1, we tune the latent vectors $\{c_i\}_{i=1}^n$ and bias b to minimize a loss function posed over the observed entries of the miscibility matrix, $\{m_{ij} : \{i, j\} \in \Omega_{\text{obs}}\}$, and the solution graph G :

$$\begin{aligned} \ell(c_1, \dots, c_n, b) = & - \sum_{\{i,j\} \in \Omega_{\text{obs}}} [m_{ij} \log(\sigma(c_i \cdot c_j + b)) + \\ & (1 - m_{ij}) \log(1 - \sigma(c_i \cdot c_j + b))] \\ & + \lambda \sum_{i=1}^n \|c_i\|^2 + \gamma \sum_{\{i,j\}: \{v_i, v_j\} \in \mathcal{E}} \|c_i - c_j\|^2 \quad (4) \end{aligned}$$

The loss function comprises three terms:

- **cross-entropy loss.** This term incentivizes the model predictions via eq 1 to match the observed miscibility outcomes in the training data $\{m_{ij} : \{i, j\} \in \Omega_{\text{obs}}\}$. If a pair of solutions i and j are observed to be miscible, i.e., $m_{ij} = 1$ (immiscible, i.e., $m_{ij} = 0$), then this term penalizes output of the model in eq 1 straying far below 1.0 (above 0.0). From a probabilistic perspective, the cross-entropy loss follows from minimizing the negative log-likelihood of the outcomes in the training data under the probabilistic (likelihood) model in eq 1.
- **2-norm regularization.** To prevent overfitting, this term penalizes latent compound solution vectors with a large magnitude. The hyperparameter $\lambda > 0$ modulates the strength of the 2-norm regularization.
- **graph-based regularization.** To promote latent solution vectors whose solutes belong to the same category to lie closeby in latent space, this term penalizes pairs of solution vectors that belong to the same category (hence, an edge exists in the solution graph G) from being distal in latent space. This term is a means of building our prior knowledge “solutions whose solutes belong to the same category tend to have similar miscibility behavior” into the model. The hyperparameter $\gamma > 0$ modulates the strength of the graph-based regularization.

Note, the loss function does not concern the miscibility outcome of a solution with itself (a solution is always miscible with itself, so $m_{ii} = 1$).

The loss function l in eq 4 can be minimized by gradient descent. One epoch of gradient descent comprises using the gradients to update b and $\{c_i\}_{i=1}^n$ in shuffled order. The relevant gradients are, similar to those in logistic regression,⁵⁵

$$\begin{aligned} \nabla_{c_i} l = & \sum_{j: \{i,j\} \in \Omega_{\text{obs}}} [\sigma(c_i \cdot c_j + b) - m_{ij}] c_j + 2\lambda c_i \\ & + 2\gamma \sum_{j: \{v_i, v_j\} \in \mathcal{E}} (c_i - c_j) \end{aligned} \quad (5)$$

$$\nabla_b l = \sum_{\{i,j\} \in \Omega_{\text{obs}}} (\sigma(c_i \cdot c_j + b) - m_{ij}) \quad (6)$$

The model in eq 1 trained with the loss function in eq 4 comprises graph-regularized matrix factorization (GR-LMF). Note, the solution graph G is only used in the training stage, not the imputation stage. See ref 45 for more details on GR-LMF.

Hyperparameters. Our GR-LMF model contains four hyperparameters: (1) k , the dimension of the latent solution space; (2) λ , the two-norm regularization parameter; (3) γ , the graph-based regularization parameter; and (4) t , the classification threshold that balances false positives and false negatives. We optimize k , λ , and γ via a random search paired

with 3-fold class-stratified cross-validation of the observed entries $\{m_{ij} : \{i, j\} \in \Omega_{\text{obs}}\}$ and select the values that give the largest mean balanced accuracy for imputing the validation entries. We optimize t via grid search based on balanced accuracy over the training entries.

Imputation Performance Metric: Balanced Accuracy.

As a primary metric of the imputation performance of a GR-LMF model appropriate for balanced classes, we employ the *balanced accuracy*: the average of (i) the recall of immiscible solution pairs: among those pairs of solutions that are truly immiscible, the fraction that the model correctly predicts to be immiscible; and (ii) the recall of miscible solution pairs: among those pairs of solutions that are truly miscible, the fraction that the model correctly predicts to be miscible.

COMPUTATIONAL METHODS

Data. To test our approach, we used the experimental data from Peacock et al.²⁰ This data set provides (i) the complete miscibility matrix M_{complete} containing all pairwise mixing outcomes of $n = 68$ aqueous solutions of distinct compounds at compound-specific concentrations (1559 miscible and 719 immiscible pairs) near room temperature and (ii) for the solution graph G , the category to which each compound belongs: 46 polymers, 11 surfactants, 8 proteins, and 3 salts. See Figure S2 for the complete miscibility matrix M_{complete} for all $n(n-1)/2 = 2278$ pairs of solutions. For the purpose of demonstrating missing value imputation, we generate, from M_{complete} , a simulated incomplete miscibility matrix, $M^{(\theta)}$; decoration with θ indicates the fraction of missing entries in the matrix.

Simulating Incomplete Experiments to Construct an Incomplete Miscibility Matrix. To simulate hypothetical incomplete experimentation, we construct an $n \times n$, symmetric incomplete miscibility matrix $M^{(\theta)}$, where θ is the fraction of missing entries in the matrix, as follows. First, we randomly partition the complete set of $n(n-1)/2$ pairs of miscibility observations $\{(\{i, j\}, m_{ij}) : \{i, j\} \in \Omega_{\text{all}}\}$ of Peacock et al.²⁰ into an *observed* set $\{(\{i, j\}, m_{ij}) : \{i, j\} \in \Omega_{\text{obs}}\}$ (fraction: $1 - \theta$) and *unobserved* set $\{(\{i, j\}, m_{ij}) : \{i, j\} \in \Omega_{\text{all}} \setminus \Omega_{\text{obs}}\}$ (fraction: θ). We stratified the split according to the miscibility outcome to preserve the class distribution. We then construct the incomplete miscibility matrix $M^{(\theta)}$ by placing the miscibility outcomes belonging to the observed set in the appropriate entries; the remaining entries are set as missing. The unobserved set serves as hold-out test data, not used for training the GR-LMF model, nor for tuning its hyperparameters. Philosophically, this train/test partition of the miscibility outcomes mimics the situation where we (1) possess an incomplete miscibility matrix, train a GR-LMF model, and make predictions on the missing miscibility outcomes and then (2) go into the lab to conduct the miscibility experiments needed to complete the miscibility matrix and compare these observations to the predictions to assess the performance of the GR-LMF model.

Note, the solution graph G is static. Regardless of θ and which entries of the miscibility matrix $M^{(\theta)}$ are missing, G contains n nodes, one for each solution, and any two solutions are joined by an edge if and only if their solute belongs to the same category (polymer, surfactant, protein, or salt).

GR-LMF Training and Hyperparameter Tuning. We examined both ordinary gradient descent and Adam⁵⁶ to minimize the loss function. Preliminary investigations showed that ordinary gradient descent was sensitive to the learning

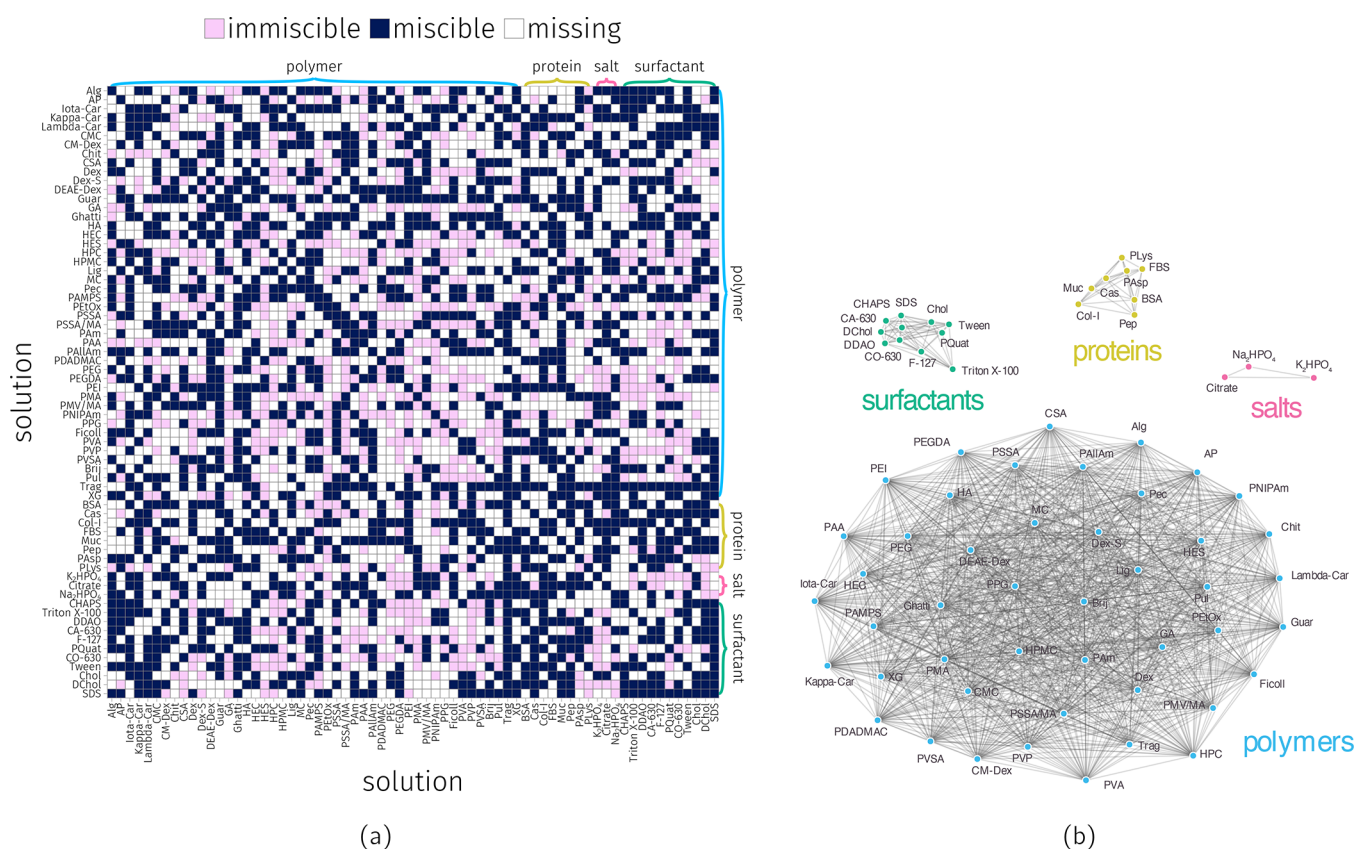

Figure 2. Data for the miscibility matrix completion problem. (a) An incomplete miscibility matrix $M^{(\theta)}$ with a fraction $\theta = 0.4$ missing entries. Entry (i, j) indicates the miscibility of a pair of solutions of compounds i and j . (b) Solution graph G indicating relationships (edges) between the solutions (nodes) based on the category of their solutes.

rate, resulted in oscillations in the loss for large learning rates, and required ~ 350 epochs to converge. In contrast, Adam was insensitive to the choice of learning rate and required fewer than 250 epochs for convergence, and therefore was a superior choice (see Figure S4).

We determined optimal GR-LMF hyperparameters k , γ , and λ through random search over 25 hyperparameter sets independently drawn from a uniform distribution over $\{2, 3\}$, $[0, 0.1]$, and $[0, 1]$, respectively. (Our choice to limit the number of latent vector dimensions to two or three was motivated by (i) the ability to visualize the vectors and (ii) precedent from Hansen solubility theory,⁵⁷ which describes solute–solvent interactions in terms of a 3-dimensional representation.) We make a 3-fold split of the observed entries in $M^{(\theta)}$ for cross-validation. Then, we select the hyperparameter set among the 25 that, when a GR-LMF model with these hyperparameters is trained on two of the folds of the observed entries, yields the largest (mean over three models) balanced accuracy for imputing miscibilities in the remaining fold serving as the validation set. The classification threshold t is tuned based on grid search, using balanced accuracy over the train set.

Finally, once the optimal hyperparameters k^* , γ^* , and λ^* are found, we train a new GR-LMF model, the *deployment* model, based on hyperparameters k^* , γ^* , and λ^* , on all of the observed entries in the miscibility matrix $M^{(\theta)}$.

Baseline Models. Compound-Category-Informed Guessing. For each pair of compound categories $\{x, x'\}$ with $x, x' \in \{\text{protein, polymer, surfactant, salt}\}$, we find all observed entries in the training miscibility matrix that constitute an x – x'

mixture and compute the fraction of these that are miscible, $\theta_{\text{miscible}}(\{x, x'\})$. Now, suppose we are given a new pair of solutions whose solutes belong to categories x_{new} and x'_{new} and whose (im)miscibility label is missing. For this baseline, we assign a miscible label with probability $\theta_{\text{miscible}}(\{x_{\text{new}}, x'_{\text{new}}\})$ and immiscible label with probability $1 - \theta_{\text{miscible}}(\{x_{\text{new}}, x'_{\text{new}}\})$.

Ordinary Matrix Factorization (MF). To develop an ordinary LMF deployment model, we employ the same procedure as for GR-LMF but with $\gamma := 0$ to turn off the graph-regularization term in the loss function in eq 4.

Random Forest (RF). Conceptually, the input to the random forest (RF) classifier is a vector representing a pair of solutions of compounds, and the output is a prediction of either miscible (1) or immiscible (0). As a vector representation of a given solution of a compound, we use (i) the physicochemical features compiled from PubChem²² by Peacock et al.²⁰ monomer and polymer molecular weight, the log of the predicted octanol–water partition coefficient, hydrogen bond donor and acceptor counts, and complexity, (ii) the concentration of the compound in the solution, and (iii) a one-hot encoding of the category (polymer, protein, surfactant, salt) of its solute. Note, since the compounds could not be fully annotated with group (i) features, we used the imputed features based on an 8-nearest-neighbors algorithm from Peacock et al.²⁰ This gives a length-11 feature vector for each solution. To represent a *pair* of solutions, we concatenate the vector representations of the two compounds, giving a 22-dimensional input to the RF. We encourage the predictions of the RF to be invariant to the order in which the pair of solutions is presented through data augmentation: each

solution pair in the training data set gives two training data points, corresponding with the two permutations of the solution vectors concatenated to form the input. For a fair comparison with GR-LMF, we tune the classification threshold t for the RF (used to map the set of binary votes by the trees to a single binary output) to maximize the balanced accuracy of the observed miscibilities. We used the RF implementation in `scikit-learn` version 1.2.2 with default settings (100 trees grown to the maximum depth, Gini impurity for splits, five randomly selected features as candidates for each split).⁵⁸

Code and Data. All Julia⁵⁹ code to reproduce our plots in `Makie.jl`⁶⁰ is available at github.com/SimonEnsemble/miscibility_matrix_factorization. The raw miscibility data is also on our Github repo in comma-separated-value (.csv) format, which we reformatted from the Supporting Information of Peacock et al.²⁰ The required calculations are modest for this scale of data; on a 2020 Macbook Pro M1 laptop, training a single GR-LMF model requires less than 1 s of runtime, and our entire hyperparameter sweep requires less than 1 min.

RESULTS AND DISCUSSION

A GR-LMF Case Study: $\theta = 0.4$. For a demonstration and to gather insights, we present a case study where we train, test, and analyze a GR-LMF model on one instance of an incomplete miscibility matrix $M^{(\theta)}$ with 40% missing values ($\theta = 0.4$).

The incomplete miscibility matrix $M^{(0.4)}$ is shown in Figure 2a. The rows and columns are labeled by the compounds they represent and sorted by compound category (polymer, protein, salt, surfactant). Each entry is colored according to the miscibility outcome of that pair of compound solutions: immiscible (0), miscible (1), or missing. Note, the matrix is symmetric, and miscibility is more common than immiscibility.

The solution graph G is shown in Figure 2b. Each node is labeled by the solute in the solution that it represents. Each pair of nodes, representing a pair of solutions, shares a color and is joined by an edge if and only if the corresponding solutes belong to the same category (polymer, protein, salt, surfactant). The induced subgraph containing a subset of nodes whose solutes belong to a certain category is complete. The edges in the solution graph G indicate relationships between the solutions and thus between the rows/columns in the miscibility matrix $M^{(\theta)}$.

We trained and tuned the hyperparameters of a GR-LMF on the observed entries in the incomplete miscibility matrix $M^{(0.4)}$ and solution graph G . The optimal hyperparameters were $k^* = 3$, $\gamma^* = 0.007$, and $\lambda^* = 0.09$. Figure S5 shows the assessed hyperparameter sets.

We evaluated the imputation performance of the deployment GR-LMF model by comparing the true miscibility outcomes, which were held out as missing during training and hyperparameter tuning, to the imputed values by the deployment GR-LMF model via eq 1. Figure S6 shows the imputed miscibility matrix. The model does not perfectly discriminate between the two outcomes (Figure S7), so the choice of threshold t will depend on the evaluation metric. The choice of balanced accuracy is a compromise between the recall of the two classes, which is appropriate because of the class imbalance in this data set. The confusion matrix for the missing entries is shown in Figure 3a. The GR-LMF achieved a balanced accuracy of 75%.

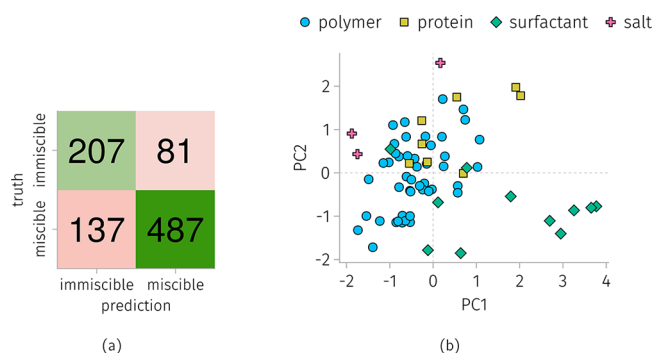

Figure 3. GR-LMF results for $M^{(\theta=0.4)}$. (a) Confusion matrix for imputation of unobserved test entries of the miscibility matrix. (b) The first two principal components of the learned latent solution vectors, $\{c_i\}$. This GR-LMF model was trained on the observed data in Figure 2 with optimized hyperparameters k^* , λ^* , and γ^* .

The relative location of the learned vectors in latent space is indicative of the predicted miscibility of the solutions they represent, so visualizing them can help us interpret the GR-LMF model. Figure 3b shows the first two principal components of the latent solution space, where each point represents a compound. (Alternatively, Figure S9 shows the latent vectors in 3D.) The shapes and colors of the points indicate the categories to which each solute belongs. The latent vectors are clustered by solute category, in part due to the graph-regularization ($\gamma > 0$). Without the graph-regularization term ($\gamma := 0$), the latent vectors of the solutions still display some clustering according to category (see Figure S10), but it is weaker than if the prior information about solute categories is included through G . The relative orientation of the latent vectors also describes the general trends in miscibility. For example, in Figure 3b, the latent vectors of the salts (pink crosses) tend to point in the opposite direction of those of the surfactants (green diamonds). Correspondingly, surfactant–salt mixtures in the data set are the most likely to be immiscible compared to other pairs of distinct compound categories (see Figure S3). Similarly, most protein vectors (yellow squares) point in a similar direction and thus tend to be miscible with each other, at least within this data set. These trends are also illustrated in the visualization of the matrix C (eq 2) whose columns contain the c_i vectors (see Figure S8).

Imputation Performance Comparisons. We investigate how the performance of GR-LMF for miscibility matrix completion compares against the baseline LMF and RF methods as a function of experimental incompleteness, θ . Figure 4 displays the distribution of balanced accuracy of GR-LMF, LMF, RF, and compound-category-informed guessing for imputing missing miscibilities over 10 realizations of incomplete miscibility matrices $M^{(\theta)}$'s for different missing fractions of miscibility experiments $\theta \in \{0.2, 0.5, 0.8\}$.

How does performance vary over the random process of incomplete experimentation, i.e., over different missing value patterns in the incomplete miscibility matrix $M^{(\theta)}$? We conducted 10 simulations of incomplete experimentation to generate 10 realizations of incomplete miscibility matrices $M^{(\theta)}$ and then trained and hyperparameter-tuned the models on each $M^{(\theta)}$ (and G , which is static). The box plots in Figure 4 show the distribution of balanced accuracy of each model over these 10 realizations. For each θ , the standard deviation of the balanced accuracy of the GR-LMF is less than 3.1%.

Figure 4. Performance of graph-regularized matrix factorization (GR-LMF), ordinary matrix factorization (LMF), random forest (RF) classifier, and compound-category-informed guessing. Box plots show the distribution of balanced accuracy for missing miscibility imputation (the hold-out test set) over 10 realizations of the incomplete miscibility matrix (i.e., different missing value patterns). The three panels correspond to different fractions of the missing values, θ , in the miscibility matrix.

How does performance depend on experimental incompleteness, i.e., on the fraction θ of entries missing in the miscibility matrix $M^{(\theta)}$? We trained and hyperparameter-tuned the models for three different levels of matrix incompleteness, $\theta \in \{0.2, 0.5, 0.8\}$ (10 runs each). Intuitively, the imputation accuracy for each model diminishes as the missing fraction θ increases. GR-LMF improves upon LMF ($\gamma := 0$) dramatically when the matrix is very incomplete ($\theta = 0.8$). This shows that the information provided by the solution graph G is beneficial for the imputation task.

How does GR-LMF compare to the traditional supervised learning approach of predicting the miscibility of a pair of solutions from hand-engineered features of the compounds? GR-LMF outperforms the random forest classifier across all θ investigated; the gap in balanced accuracy is more prominent at the largest fraction of missing entries $\theta = 0.8$. This seems unexpected because one would think that the input features to the RF encode meaningful physicochemical aspects of the solutes pertinent to miscibility—especially relevant when data is scarce. The RF has 22 input features but, even in the case of $\theta = 0.8$, has access to 900 examples, so its poor performance is not likely to be due to overfitting. This implies that GR-LMF learns latent representations of the compound solutions that better describe the pairwise miscibility than the physicochemical features provided to the RF. That even ordinary LMF outperforms RF when the matrix is more complete underscores this.

What features of the solutions are most important for the predictions of the RF model? Figure S11 shows the permutation-based importance of each feature of the solutions input to the RF. The balanced accuracy on the test set decreased the most when shuffling the feature indicating the concentration of the solute in the solution. The number of H-bond donor/acceptor sites was the second-most important feature.

How do the different models perform for miscibility imputation according to different metrics? Using the hyperparameters determined by cross-validation on balanced accuracy, we assessed each model type on accuracy, precision, recall, and F1 score (harmonic mean of precision and recall) (see Figure S12). Generally, GR-LMF performs comparably or better than the other methods according to the metrics

examined, with the exceptions of recall scores at all completions and F1 scores at $\theta = 0.8$. This is unsurprising, as the GR-LMF hyperparameters were not tuned for these metrics. This illustrates the general quality of GR-LMF across other performance metrics, despite not explicitly tuning for those metrics.

Strengths and Weaknesses of GR-LMF. Beneficially, GR-LMF does not require any feature engineering of the solutes, except for assigning them to general categories. This is advantageous because feature engineering of the solutes is difficult: it requires prior physical insight into solute features that are related to miscibility and the measurement or computation of those features for a diverse set of solutes. As we show above, the latent vector representation of the solution learned by GR-LMF directly from incomplete experimental miscibility observations is superior at capturing the underlying physicochemical features of the solutes that determine pairwise miscibility, even when most of the pairs of mixtures have not been observed.

However, *learning* as opposed to engineering features of the solutes is also a weakness of MF methods, known as the “cold-start” problem. Because the latent solution vector is learned from miscibility experiments, the model cannot make predictions on a new solution without some initial miscibility experiments involving that solution. However, as we showed in the previous section, GR-LMF can perform well at large θ , so not many examples are needed.

Another weakness of our GR-LMF model is that it does not trivially generalize to capture the temperature or concentration dependence of miscibility. (In contrast, with RF one would simply add an additional concentration or temperature feature to the input and retrain the model.) In principle, GR-LMF can be modified to capture the temperature and concentration dependence of miscibility by (1) endowing solutions of the same solute at different concentrations and temperatures with distinct solution vectors and (2) using a concentration- and temperature-dependent kernel function to construct edge-weights in the solution graph. Alternatively, matrix factorization could be used to determine parameters in a physically motivated equation that captures the concentration and temperature dependence, similar to Damay et al.’s approach for predicting temperature-dependent activity coefficients.³³

CONCLUSIONS

In this work, we described and demonstrated a data-driven method, graph-regularized matrix factorization (GR-LMF), to impute missing entries in a pairwise miscibility matrix (rows/columns = solutions of a compound, entries = miscibility). As opposed to hand-engineering feature vectors of the solutions (which may be difficult), GR-LMF learns latent vector representations of each solution from the observed entries in the miscibility matrix and a solution graph indicating the categories to which each solute belongs. These latent vectors then may be used to impute the missing entries in the incomplete miscibility matrix, which, in principle, eliminates the need for a chemist to perform all of the pairwise experiments during an initial screening. GR-LMF outperforms both ordinary LMF and a random forest classifier that predicts miscibility based on physicochemical features of the compounds in the solutions. Unsurprisingly, the performance of GR-LMF diminishes with the fraction of missing entries in the miscibility matrix, but even when 80% of the data are missing, it outperforms the competing imputation methods.

Our machine learning study was enabled by the open miscibility data set of Peacock et al.²⁰ To both improve and expand the capabilities of data-driven models for ATPS prediction, we encourage the generation and curation of large, FAIR (findable, accessible, interoperable, and reusable⁶¹) miscibility data sets. Though subject to error, natural language processing could also be used to mine existing miscibility data from the scientific literature⁶² (to our knowledge, only one other sizable miscibility data set of 34 polymers and surfactants has been generated⁶³). On the other hand, the advantage of using a single data set is that it avoids interlab variations, such as variations in purity or protocol, that might make the data less useful for machine learning.⁶⁴ The relatively simple nature of the experimental process (mixing aqueous solutions) and characterization (via microscopic image analysis²¹) lends itself to laboratory automation for generating a large data set.

Our ideas for extensions and future directions for miscibility matrix completion are the following: (1) Extend our model in eq 1 to include the dependence of miscibility on temperature and concentration of the solute; this effort is predicated on the availability of miscibility data at different temperatures and containing solutions of each compound at different concentrations. (2) Leverage Bayesian probabilistic matrix factorization^{32,65} to develop a GR-LMF model that quantifies uncertainty in its predictions. (3) Use uncertainty quantification to guide the selection of miscibility experiments that provide the most information for improving imputation.⁶⁶ (4) Impose graph-regularization through a graph with weighted edges, whose weights are determined by a kernel that continuously quantifies the similarity between the compounds. (5) Extend to ternary and higher-component mixtures—also predicated upon the availability of higher-component miscibility data; this corresponds to a known problem of tensor decomposition.⁶⁷ (6) Investigate the effect that experimental selection bias^{68,69} may have on the performance of miscibility matrix factorization.
